The use of orthonormal wavelet basis functions for solving singular integral scattering equations is investigated. It is shown that these basis functions lead to sparse matrix equations which can be solved by iterative techniques. The scaling properties of wavelets are used to derive an efficient method for evaluating the singular integrals. The accuracy and efficiency of the wavelet transforms is demonstrated by solving the two-body T-matrix equation without partial wave projection. The resulting matrix equation which is characteristic of multiparticle integral scattering equations is found to provide an efficient method for obtaining accurate approximate solutions to the integral equation. These results indicate that wavelet transforms may provide a useful tool for studying few-body systems.

I. INTRODUCTION

Few-body systems provide a useful tool for studying the dynamics of hadronic systems. The combination of short-ranged interactions and finite density means that the dynamics of complex hadronic systems can be understood by studying the dynamics of few-degree of freedom sub-systems. Few-body systems are simple enough to perform nearly complete high-precision measurements and to perform ab-initio calculations that are exact to within the experimental precision. This clean connection between theory and experiment has led to an excellent understanding of two-body interactions in low-energy nuclear physics, and a good understanding of the three-body interactions.

Our knowledge of low-energy hadronic dynamics is largely due to the interplay between experimental and computational advances. A complete understanding of even the simplest few-hadron system requires measurements of a complete set of spin observables which have small cross sections and require state of the art detectors. At the same time, the model calculations with realistic interactions are limited by computer speed and memory. In addition the equations are either singular or have complicated boundary conditions which require specialized numerical treatments.

One of the most interesting energy scales is the one where the natural choice of few-body degrees of freedom changes from nucleons and mesons to sub-nuclear degrees of freedom. The QCD string tension or nucleon size suggest that the relevant scale for the onset of this transition is about a GeV. A consistent dynamics of hadrons or sub-nuclear particles on this scale must be relativistic; a Galilean invariant theory cannot simultaneously preserve momentum conservation in the lab and center of momentum frames if the initial and final reaction products have different masses. Relativistic dynamical models are most naturally formulated in momentum space. This is due to the presence of momentum-dependent Wigner and/or Melosh rotations as well as square roots that appear in the relationship between energy and momentum.

Non-relativistic few-body calculations formulated in configuration space with local potentials have the advantage that the matrices obtained after discretizing the dynamical equations are banded, thus reducing the size of the numerical calculations. Equivalent momentum-space calculations lead to dense matrices of comparable dimensions. In addition, the embedding of the two-body interactions in the three-body Hilbert space leads to non-localities. Realistic relativistic three-body calculations are just beginning to be solved [1, 2]. Numerical methods that can reduce the size of these calculations could make relativistic calculations of realistic systems more tractable.

In this paper we explore the use of wavelet basis functions to reduce the size of momentum space scattering calculations. The resulting linear system can be accurately approximated by a linear system with a sparse kernel. It is our contention that the use of this sparse kernel results in a reduction in the size of the numerical calculation that is comparable to the corresponding configuration space calculations. The advantage is that the wavelet methods can be applied in momentum space and are not limited to local interactions.

The long-term goal is to apply wavelet methods to solve the relativistic three-body problem. In a previous paper [3], we tested this method to solve the non-relativistic Lippmann-Schwinger equation with a Malfliet Tjon V potential. In this test problem, the s-wave K-matrix was computed. The wavelet method led to a significant reduction in the size of the problem. We found that 96% of the matrix elements of the kernel of the integral equation could be eliminated leading to an error of only a few parts in a million.

In this paper, we test the wavelet method on the same
gular two-variable integral equation, which has the same
development equations with partial waves. It is simpler than the
full three-body calculation, but is a much larger calculation
than was needed in Ref. [3]. In addition, computations
that employ conventional methods [4] are available
for comparison. In solving this problem it is necessary
to address issues involving the storage and computations
with large matrices.

One well known use of wavelets is in the data compres-
sion algorithm used in JPEG files [5]. Our motivation
for applying wavelet methods to scattering problems is
based on the observation that both a digital photograph
and a discretized kernel of an integral equation are two-
dimensional arrays of numbers. If wavelets can reduce
the size of a digital image, they should have a similar
effect on the size of the kernel of an integral equation.

Given the utility of wavelets in digital data processing,
it is natural to ask why they have not been used ex-
tensively in numerical computations in scattering. One possible reason is because there is a non-trivial learning
curve that must be overcome for a successful application
to singular integral equations. A relevant feature is that
the basis functions have a fractal structure; they are solu-
tions to a linear renormalization group equation and thus
have structure on all scales. Numerical techniques that
exploit the local smoothness of functions do not work ef-
effectively with functions that have structure on all scales.

In [3], we concluded that these limitations could be
overcome by exploiting the renormalization group trans-
formation properties of the basis functions in numeri-
cal computations. These equations were used to com-
pute moments of the basis functions with polynomials.
These moments were used to construct efficient qua-
drature methods for evaluating overlap integrals. In addi-
tion, these moments could be combined with the renor-
malization group equations to perform accurate calcula-
tions of the types of singular integrals that appear in scat-
tering problems. A key conclusion of [3] was that wavelet
methods provide an accurate and effective method for
solving the scattering equations. In addition, the ex-
pected reduction in the size of the numerical problem
could be achieved with minimal loss of precision.

There are many kinds of wavelets. In [3] we found
that the Daubechies-3 [6] wavelets proved to be the most
useful for our calculations. Numerical methods based on
wavelets utilize the existence of two orthogonal bases for
a model space. The two bases are related by an orthog-
onal transformation. The first basis, called the father
function basis, samples the data by averaging on small
scales. It is the numerical equivalent of a raw digital pho-
tograph. The orthogonal transformation is generated by
filtering the coefficients of the father function basis into
equal numbers of high and low frequency parts. The high
frequency parts are associated with another type of basis
function known as the mother function. The same filter is
again applied only to the remaining low frequency parts,
which are divided into high and low frequency parts. This
is repeated until there is only one low frequency coeffi-
cient. This orthogonal transformation and its inverse can
be generated with the same type of efficiency as a fast
Fourier transform. The new basis is called the wavelet
basis.

For the Daubechies-3 wavelets, both sets of basis func-
tions have compact support. The support of the father
function basis functions is small and is determined by the
resolution of the model space. The support of the wavelet
basis functions is compact, but occurs on all scales be-
tween the finest resolution and the coarsest resolution.

The father function for the Daubechies-3 wavelets has
the property that a finite linear combination of such func-
tions can locally pointwise represent a polynomial of de-
tree. Integrals over these polynomials and the scaling
basis functions can be done exactly and efficiently using
a one-point quadrature.

The mother functions have the property that they are
orthogonal to polynomials of degree two. This means
that the expansion coefficient for a given mother basis
function is zero if the function can be well-approximated
by a polynomial on the support of the basis function. It
is for this reason that most of the kernel matrix elements
in this representation are small. Setting these small co-
efficients to zero is the key approximation that leads to
sparse matrices.

Some of the properties that make the Daubechies
wavelets interesting for numerical computations are

- The basis functions have compact support.
- The basis functions are orthonormal.
- The basis functions can pointwise represent polyno-
mials of degree two.
- The wavelet transform automatically identifies the
  important basis functions.
- There is a simple one point quadrature rule that is
  exact for local polynomials of degree two.
- These are accurate methods for computing the sin-
gular integrals of scattering theory.
- The basis functions never have to be computed.

The above list indicates that wavelet bases have many
advantages in common with spline bases, which have
proven to be very useful in large few-body calculations.
Both the spline and wavelet basis functions have com-
pact support, which allows them to efficiently model local
structures, both provide pointwise representations of low-
degree polynomials, both can be easily integrated using
simple quadrature rules, and both can be accurately in-
tegrated over the scattering singularity. One feature that
distinguishes the wavelet method from the spline method
is that the wavelet transform automatically identifies the
important basis functions that need to be retained. With
spline collocation method with the stability of the Galerkin method.

In the next section we give an overview of the properties of wavelets that are used in our numerical computations. Our model problem is defined in section three. The methods of section two are used in section four to reduce the scattering integral equation in section three to an approximate linear system. The transformation to a sparse-matrix linear system and the methods used to solve the linear equations are discussed in section five. The considerations discussed in this section are important for realistic applications. The results of the model calculations are discussed and compared to the results of partial-wave calculations in section six. Our conclusions are summarized in section seven. The complex bi-conjugate gradient algorithm that was used to solve the resulting system of linear equations is outlined in the Appendix.

II. WAVELET PROPERTIES

In our work, we use Daubechies’ original bases of compactly supported wavelets [6]. In addition to their simplicity, these functions possess many useful properties for numeric calculations, which are discussed at the end of this section.

A. General Wavelet Analysis

There are two primal basis functions called the father, \( \phi \), and mother, \( \psi \). The primal father function is defined as the solution of the homogeneous scaling equation

\[
\phi(x) = \sqrt{2} \sum_{l=0}^{2K-1} h_l \phi(2x - l),
\]

with normalization

\[
\int \phi(x) dx = 1.
\]

The primal mother function is defined in terms of the father by a similar scaling equation,

\[
\psi(x) = \sqrt{2} \sum_{l=0}^{2K-1} g_l \phi(2x - l),
\]

TABLE I: Scaling Coefficients for Daubechies-3 Wavelets

| \( h_l \) | \( (1 + \sqrt{10} + \sqrt{5} + 2\sqrt{x})/\sqrt{16} \) |
| \( h_1 \) | \( (5 + \sqrt{10} + 3\sqrt{5} + 2\sqrt{10})/\sqrt{16} \) |
| \( h_2 \) | \( (10 - 2\sqrt{10} + 2\sqrt{5} + 2\sqrt{10})/\sqrt{16} \) |
| \( h_3 \) | \( (10 - 2\sqrt{10} + 2\sqrt{5} + 2\sqrt{10})/\sqrt{16} \) |
| \( h_4 \) | \( (5 - \sqrt{10} - 3\sqrt{5} + 2\sqrt{10})/\sqrt{16} \) |
| \( h_5 \) | \( (1 + \sqrt{10} + \sqrt{5} + 2\sqrt{10})/\sqrt{16} \) |

where

\[
g_l = (-1)^l h_{2K - 1 - l}.
\]

The parameter \( K \) is the order of the Daubechies wavelet and the \( h_l \) are a unique set of numerical coefficients that satisfy certain relations [6] such as orthogonality of basis functions. We employ wavelets of order \( K = 3 \), henceforth called Daubechies-3 wavelets. The numerical values of the \( h_l \) are given in Table I.

Equation (1) is the most important in all of wavelet analysis, as all the properties of a wavelet basis are determined by the so-called filter coefficients, \( h_l \). A simple property that follows from the \( h_l \) is that the father and mother function both have compact support on the interval \((0, 2K - 1)\). All other basis functions are related to the primal father and mother by means of dyadic (power of two) scale transformations and unit translations,

\[
\phi_{j,k}(x) := 2^{-j/2} \phi(2^j x - k),
\]

\[
\psi_{j,k}(x) := 2^{-j/2} \psi(2^j x - k).
\]

To solve the two-dimensional integral equation for the T-matrix we need to construct a two-dimensional basis in terms of wavelet functions. The simplest method is to construct a direct-product basis of the one-dimensional functions

\[
\phi_{m,l}(x) \phi_{n,k}(y), \quad \phi_{m,l}(x) \psi_{n,k}(y), \quad \psi_{m,l}(x) \phi_{n,k}(y), \quad \text{and} \quad \psi_{m,l}(x) \psi_{n,k}(y).
\]

The primal versions of these four basis function types for the Daubechies-3 wavelets are shown in Fig. 1. The complex pointwise structure of the basis functions tends to obscure their ability to accurately and efficiently represent smooth functions. Fortunately, the pointwise structure never appears in calculations, since all calculations are made in terms of the simple scaling equation (1).

B. Equivalent Representations and Wavelet Transforms

If one includes wavelets of all scales, then one can obtain a basis for \( L^2(\mathbb{R}) \). In practice however, one chooses a fine approximation scale \( J \) and constructs an approximation basis with respect to this scale. At any scale, there
are two equivalent bases in terms of wavelet functions. The first basis consists of translates of the father function on the finest scale \( J \). The second basis consists of the father functions on all intermediate scales \( j = 0, \ldots, J - 1 \). So, for any function we have two equivalent approximations given by

\[
\begin{align*}
    f(x) &= \sum_l a_l \phi_{J,l}(x) \\
    &= \sum_l a_l^{0} \phi_{0,l}(x) + \sum_{j=0}^{J-1} \sum_l d_{j,l} \psi_{j,l}(x).
\end{align*}
\]

(7)

In two dimensions, the two equivalent representations are given by the direct product of the one-dimensional representations, which gives us the four types of basis functions in equation (6). It turns out that the first representation is typically dense while the second can often be truncated to a sparse representation by eliminating expansion coefficients with a magnitude below some certain threshold. This is because the father functions can exactly represent polynomials of degree \( K - 1 \) while the mother functions are orthogonal to such polynomials [6]. Specifically,

\[
\int x^k \psi(x) dx = 0, \quad 0 \leq k \leq K - 1
\]

(8)

Thus, for any function that is well-represented by low degree polynomials on the scale \( J \), most of the coefficients \( d_{j,l} \) in the second representation will be small. These small coefficients can be eliminated with a local error of \( O(\epsilon) \), where \( \epsilon \) is the threshold of the truncation. A fast orthogonal transformation known as the discrete wavelet transform [7] links the two bases given above. This allows us to compute projections in the first basis where the single scale and single type of basis function make the approximations accurate and efficient. Then we can apply the discrete wavelet transform to quickly produce the sparse basis, which is useful for solving linear systems.

C. Application of the Scaling Equation

Now, we briefly discuss some of the useful results that follow from the scaling equation (1). For a more detailed treatment see [3, 8]. First we consider the moments of the father function defined by

\[
\langle x^k \rangle := \int x^k \phi(x) dx.
\]

(9)

Applying the scaling equation (1) to (9) gives

\[
\langle x^k \rangle = \frac{1}{2^k} \sum_l h_l \sum_{m=0}^k \left( \frac{k}{m} \right) t^{k-m} \langle x^m \rangle.
\]

(10)

This recursion relation, along with the normalization condition, \( \langle x^0 \rangle := 1 \), can be used to compute all of the moments of the father function in terms of the filter coefficients, \( h_l \). These moments can be used to construct quadrature rules, which are used to approximate the projection of an arbitrary function, \( f(x) \), onto a wavelet basis. We employ the simplest such quadrature, the one point quadrature [10]. This quadrature is based on the identity \( \langle x^2 \rangle = \langle x \rangle^2 \) and results in a local error of \( O(f^{(3)}(x)) \).

It is also important in applications to consider the case where the interval of integration is finite. Specifically, we consider integrals over left-hand and right-hand endpoints of the form [11]

\[
\begin{align*}
    \langle x^k \rangle^+_m := &\int_0^\infty \phi(x-m)x^k dx, \\
    \langle x^k \rangle^-_m := &\int_{-\infty}^0 \phi(x-m)x^k dx, \\
    \Delta^+_{mn} := &\int_0^\infty \phi(x-m)\phi(x-n) dx, \\
    \Delta^-_{mn} := &\int_{-\infty}^0 \phi(x-m)\phi(x-n) dx.
\end{align*}
\]

(11)

and

(12)

Applying the scaling equation (1) to these integrals gives linear relations such as

\[
\langle x^k \rangle^+_m = 2^{-k-1/2} \sum_{l=0}^{2K-1} h_l \langle x^k \rangle^+_{2m+l}
\]

(13)

These linear systems can be solved for the cases of \( m, n = -1, -2, \ldots, -(2K - 2) \) using the previously computed moments for \( \langle x^k \rangle_m \) and the orthogonality relations for \( \Delta^+_{m,n} \).

In [3], we introduced a method for computing singular integrals of the form

\[
S_k := \int \frac{\phi(x - k)}{x + i0^+} dx,
\]

where \( 0^+ \) is a positive infinitesimal quantity. Applying the scaling equation (1), gives the degenerate linear relations

\[
S_k = \sqrt{2} \sum_{l=0}^{2K-1} h_l S_{2l-k}.
\]

These can be supplemented with a normalization condition

\[
-i\pi = \int_{-a}^{a} \frac{dx}{x + i0^+} = \sum_n \int_{-a}^{a} \frac{\phi(x - n)}{x + i0^+} dx = S_{n:a},
\]

which follows from the identity \( 1 = \sum_n \phi(x - n) \). Finally, we need the nonsingular integrals which can be obtained using the recursion relation (16) and the convergent expansion for large \( n \) given by

\[
S_{n:a} = \int_{-a}^{a} \frac{\phi(x - n)}{x + i0^+} dx
= \frac{1}{n} \int_{-a}^{a} \frac{\phi(y)}{1 + y/n} dy
= \frac{1}{n} \sum_{k=0}^{\infty} \frac{(-1)^k}{n} \int_{-a}^{a} \phi(y)y^k dy,
\]

where the final integrals can be calculated using the methods for equations (9) and (11). The values of the singular integrals are given in Table II.

For a more thorough and detailed discussion of these calculations and additional properties of wavelets see [3, 8].

### III. TWO-BODY T-MATRIX IN MOMENTUM SPACE

The two-body T-matrix is given by the solution to the Lippmann-Schwinger equation

\[
T = V + VG_0T,
\]

where \( V \) is the two-body potential and \( G_0 = (E + i\epsilon - H_0)^{-1} \) is the free two-body propagator. In momentum space, this equation becomes

\[
T(p', p, x') = \frac{1}{2\pi} v(p', p, x', 1) - m \int_0^\infty dp'' \frac{1}{p'\epsilon - p''^2 - p_0^2 - i\epsilon} T(p'', p, x''),
\]

where \( m \) is the mass of the particles, \( p_0 \) is the on-shell momentum, \( x' = \tilde{p}' \cdot \tilde{p}, \ x'' = \tilde{p}'' \cdot \tilde{p} \), and \( v \) is the two-body potential with the azimuthal angle dependence integrated out. For our calculations, we use a Malfliet-Tjon III potential [12] with attractive and repulsive parts. In this case, the azimuthal integration can be carried out analytically giving

\[
v(p', p, x', x) = \frac{1}{\pi} \left[ \frac{\lambda_R}{\sqrt{(p'^2 + p^2 - 2p' p x x + \mu_R)^2 - 4p'^2 p^2 (1 - x^2)(1 - x'^2)}} \right. \\
- \left. \frac{\lambda_A}{\sqrt{(p'^2 + p^2 - 2p' p x x + \mu_A)^2 - 4p'^2 p^2 (1 - x^2)(1 - x'^2)}} \right].
\]

The parameters for this potential are: \( \lambda_A = -626.8932 \) MeV fm, \( \mu_A = 1.55 \) fm\(^{-1} \), \( \lambda_R = 1438.723 \) MeV fm, \( \mu_R = 3.11 \) fm\(^{-1} \), which correspond to those used in [4]. We use
a nucleon mass such that $1/m = 41.47$ MeV fm$^2$.

In our work, we consider solutions for the half off-shell T-matrix, $T(p', p_0, x')$. Traditionally, the T-matrix is decomposed in a partial wave basis using

$$ T(p', p_0, x') = \sum_{l=0}^{\infty} \frac{2l + 1}{4\pi} T_l(p') P_l(x') $$

(22)

where the $P_l$ are Legendre polynomials. Each amplitude $T_l(p')$ must be solved for individually. For high energies, a significant number of amplitudes may need to be included to ensure convergence [4].

The magnitude squared of the on-shell T-matrix is proportional to the differential cross section. Furthermore, the on-shell partial wave amplitudes, $T_l(p_0)$, can be parameterized as

$$ T_l(p_0) = -\frac{2}{\pi} \frac{1}{m_0} e^{i\delta_l(p_0)} \sin(\delta_l(p_0)), $$

(23)

where the $\delta_l(p_0)$ are experimentally determined phase-shifts. These phase-shifts are used to fit realistic nucleon-nucleon potentials and should be accurately reproduced by any viable solution method.

**IV. WAVELET REPRESENTATION**

To solve equation (20) we need to transform the half-interval, $[0, \infty)$, corresponding to the momentum variable into a finite interval, $[-a, b]$. For computational convenience we also transform the interval, $[-1, 1]$, associated with the angular variable into the region, $[-c, d]$. For the first transformation we use the following map

$$ p(k) := \frac{b}{a} \frac{a+b}{a-b} k, \quad k(p) := \frac{ab(p-p_0)}{ap + p_0b}, $$

(24)

which maps the scattering singularity at $p'' = p_0$ to the origin. Then we have

$$ dp = \frac{b}{a} \frac{(b+a)}{(a-b)^2} dk $$

(25)

and

$$ \frac{1}{p-p_0} = \frac{a(b-k) - 1}{(a+b)p_0 k}. $$

(26)

The second mapping is the simple linear transformation

$$ x(u) := \frac{2u - d + c}{d + c}, \quad u(x) := \frac{(d + c)x + (d - c)}{2}, $$

(27)

which gives

$$ dx = \frac{2}{d + c} du. $$

(28)

We now apply these maps to equation (20) to obtain an equivalent integral equation on the rectangular region $[-a, b] \times [-c, d]$. For notational convenience we define

$$ f(p', x') := T(p', p_0, x'), $$

$$ g(p', x') := \frac{1}{\pi} v(p', p_0, x', 1), $$

(29)

and for the non-singular part of the kernel

$$ L(p', p'', x', x'') := m \frac{v(p', p'', x', x'')p''^2}{p''^2 + p_0^2}. $$

(30)

Now, we let

$$ \tilde{f}(k', u') := f(p(k'), x(u')) $$

(31)

and

$$ \tilde{g}(k', u') := g(p(k'), x(u')) $$

(32)

The last factor in this equation comes from applying equations (25), (26) and (28), which gives

$$ \frac{1}{p'' - p_0} dp'' dx'' = \frac{2}{k''} \frac{b}{d + c b - k''} dk'' du''. $$

(33)

Finally, substituting equations (31) and (32) into equation (20) gives

$$ - \int_{-a}^{b} dk'' \int_{-c}^{d} du' \tilde{L}(k', k'', u', u'') \tilde{f}(k'', u''). $$

(34)

Now, we project this equation onto the wavelet basis which results in a Galerkin type procedure. In general, one can choose a separate fine scale in each variable. For notational simplicity, we will consider the case where $J_k = J_u = J$. In this case, we approximate $\tilde{f}$ using

$$ \tilde{f}(k', u') \approx \sum_{m,n} \tilde{f}_{m,n}(k') \phi_{J,m}(u'). $$

(35)

Substituting this in (34) and multiplying by $\phi_{J,m}(k') \phi_{J,n}(u')$ and integrating over $k'$ and $u'$ gives the linear equation
\[
\sum_{m,n} N_{m',n';m,n} \tilde{f}_{m,n} = \tilde{g}_{m',n'} - \sum_{m,n} \int_{-b}^{b} \int_{-d}^{d} \int_{-c}^{c} \int_{-c}^{c} \int_{-d}^{d} \int_{-d}^{d} \phi_{J,m'}(k') \phi_{J,n'}(u') \frac{\tilde{L}(k', k'', u', u'')}{k''} \phi_{J,m}(k'') \phi_{J,n}(u'') \tilde{f}_{m,n},
\]

where

\[
\tilde{g}_{m',n'} := \int_{-b}^{b} \int_{-c}^{c} \int_{-d}^{d} u' \phi_{J,m'}(k') \phi_{J,n'}(u')
\]

and

\[
N_{m',n';m,n} := \int_{-b}^{b} \int_{-c}^{c} \int_{-d}^{d} \int_{-d}^{d} \phi_{J,m'}(k') \phi_{J,n'}(u') \phi_{J,m}(k') \phi_{J,n}(u')
\]

We can evaluate \(\tilde{g}_{m',n'}\) using the one-point quadrature [10] discussed earlier and an endpoint quadrature based on the partial moments [3]. \(N_{m',n';m,n}\) is simply the direct product of block diagonal matrices consisting of identity blocks and blocks of the form \(\Delta^\pm\) given in equation (12). The final term in equation (36) can be evaluated using the subtraction

\[
\tilde{L}_{m',n';m,n} := \int_{-a}^{b} \int_{-c}^{c} \int_{-d}^{d} \int_{-d}^{d} \phi_{J,m'}(k') \phi_{J,n'}(u') \frac{\tilde{L}(k', k'', u', u'')}{k''} \phi_{J,m}(k'') \phi_{J,n}(u'')
\]

\[
= \int_{-a}^{b} \int_{-c}^{c} \int_{-d}^{d} \int_{-d}^{d} \phi_{J,m'}(k') \phi_{J,n'}(u') \frac{\tilde{L}(k', k'', u', u'')}{k''} \phi_{J,m}(k'') \phi_{J,n}(u'') - \tilde{L}(k', 0, u', u'') \int_{-a}^{b} \phi_{J,m}(k'') \frac{k''}{k'}
\]

\[
+ \int_{-a}^{b} \int_{-c}^{c} \int_{-d}^{d} \int_{-d}^{d} \phi_{J,m'}(k') \phi_{J,n'}(u') \tilde{L}(k', 0, u', u'') \phi_{J,m}(k'') \phi_{J,n}(u'') \int_{-a}^{b} \phi_{J,m}(k'') \frac{k''}{k'}
\]

The first term in this equation is nonsingular and can be approximated using the quadrature methods previously discussed. Likewise, the \(k', u', u'\) integrations in the second term can be carried out in the same manner. The final integration over \(k''\) can be accomplished using the method following equation (16).

Thus, the problem is reduced to solving a linear system of the form

\[
\sum_{m,n} (N_{m',n';m,n} + \tilde{L}_{m',n';m,n}) \tilde{f}_{m,n} = \tilde{g}_{m',n'}.
\]

Once we have solved this equation for \(\tilde{f}_{m,n}\) we can substitute this approximate solution back into the right hand side of the original equation to obtain a refined solution.

\[\Delta^-\] and using the direct product structure of \(\mathbf{N}\). If we define

\[
h = \mathbf{N} \tilde{f},
\]

then equation (40) becomes

\[
(\mathbf{I} + \mathbf{L} \mathbf{N}^{-1}) \mathbf{h} = \mathbf{g}.
\]

If we define

\[
\mathbf{A} = \mathbf{I} + \mathbf{L} \mathbf{N}^{-1}.
\]

Then equation (42) is a simply linear system of the form

\[
\mathbf{Ah} = \mathbf{g}.
\]

This is a large dense linear system. However, as shown in equation (7), there are two equivalent representations that are linked by a fast orthogonal transformation. In two variables, the matrix representation of this transformation is simply the direct product of the one-dimensional transformation matrices that are given in many standard references [7]. If we denote this matrix as \(\mathbf{W}\) then we can transform equation (44) as

V. WAVELET TRANSFORM AND SPARSE SOLUTION

The eigenvalues of \(\Delta^+\) accumulate at 0 while those of \(\Delta^-\) accumulate at 1 as \(K\) increases [13]. This makes the matrix \(\mathbf{N}\), and consequently the right hand side of (40), numerically ill-behaved. To circumvent this difficulty we can precondition the system by inverting \(\mathbf{N}\), which is easily accomplished by inverting the two blocks \(\Delta^+\) and
\[(WAW^T)Wh = Wg.\]  

(45)

Now we make the definitions

\[\hat{A} = WAW^T, \quad \hat{h} = Wh, \quad \hat{g} = Wg.\]  

(46)

Then as mentioned in reference to equation (7) we can truncate the matrix \(\hat{A}\) by eliminating all elements with a magnitude below some certain threshold \(\epsilon\), where the error introduced is proportional to \(\epsilon\). The matrix \(\hat{A}\) can be stored in a sparse format such as compressed column format (CCS) [14], which permits both efficient storage and matrix multiplication. These savings help eliminate computationally costly writing and reading from the hard disk when solving the linear system.

To solve the sparse system we use the complex biconjugate gradient method [7, 15] which we present for general complex matrices in Appendix A. This method is a simple and effective iterative method for general sparse matrices. In addition, this method, like all iterative techniques, is readily amenable to parallel processing of the matrix multiplication. Once the solution to (45) is found, it is a simple matter to recover \(\tilde{f}\) by applying the inverse transform \(W^T\) and the inverse matrix \(N^{-1}\). In particular,

\[\tilde{f} = N^{-1}W^T\hat{h}.\]  

(47)

VI. RESULTS AND ANALYSIS

We made calculations using the Daubechies-3 wavelets at scales up to \(J = 5\) in each variable. The total number of wavelet basis functions in each variable was taken to be \(2^M\), where \(M = J + 2\). If we take \(a = c = 1\), then \(b\) and \(d\) are determined by

\[b = 2^{-J_k}(2^{M_k} - (2K - 2)) - a,\]
\[d = 2^{-J_u}(2^{M_u} - (2K - 2)) - c.\]  

(48)

Using these parameters calculations were performed at lab energies of 300 and 800 MeV to test the efficacy of the method in different energy regimes. Figure 2 shows the real and imaginary parts of the half off-shell T-matrix as a function of momentum, \(p'\), and the scattering angle, \(x' = \cos(\theta)\) at a scattering energy of 800 MeV. Daubechies-3 wavelets were used with \(M_k = M_u = 5\).

It can be seen that the real part of the T-matrix is relatively smooth, while the imaginary part does have some structure. The fact that the T-matrix is smooth with isolated structure suggests that wavelet methods should be able to efficiently compress the matrix \(\hat{A}\). Figure 3 shows the on-shell T-matrix as a function of angle, \(x' = \cos(\theta)\), at a scattering energy of 300 MeV. These calculations were made using Daubechies-3 wavelets with \(M_k = M_u = 5\). From these graphs the general smoothness of the on-shell amplitude is apparent. We can also see the forward peaking of the scattering amplitude that is expected at higher energies.

From a numerical standpoint, the first aspect of the calculation to consider is the general convergence of the method as the number of basis functions is increased. Tables III and IV illustrate the convergence of the method as the number of basis functions is increased. The quoted values are for on-shell scattering at an angle of 90° using Daubechies-3 wavelets with no truncation. From Table III, we see that the majority of improvement occurs as \(M_k\) is increased. This can be attributed to the fact that the integral over \(k''\) in the kernel is singular and thus requires more basis functions to accurately represent the dependence on this variable.

All of these calculations were made by solving the linear system (42). It is instructive to consider the behavior if one attempts to solve (40) using iterative methods.

without directly inverting $N$ first. Table V compares the error in the residual, $e_n = \| \mathbf{f}_n \| = \| \mathbf{g} - \mathbf{A}\mathbf{h}_n \|$, as a function of the number of iterations. As the number of iterations, $n$, is increased the preconditioned method converges very rapidly, while the non-preconditioned method fails to converge adequately.

Now we turn our attention to the compression of the sparse matrix and its subsequent effect on the calculation. Figure 4 displays a such a representation for scattering at 800 MeV using Daubechies-3 wavelets with $M_k = 4$, $M_n = 3$. The plot shows the location of the nonzero elements of $\mathbf{A}$ after it has been truncated at the threshold level $\epsilon = 10^{-5}$. This threshold produces a matrix with 19% of the elements of the full matrix. The ordering scheme for $\mathbf{A}$ used in the plot places the elements associated with finer scales at higher indices. The degree of sparsity increases considerably as the scale increases, which demonstrates that less and less elements are needed at finer scales.

A key advantage of wavelets is that this reduction in

the number of nonzero matrix elements significantly reduces the time required to solve the linear system. For the biconjugate gradient method, each iteration requires two matrix multiplications, which take a time proportional to the number of nonzero elements in the matrix. Thus, a reduction in the number of nonzero elements reduces the solution time by a corresponding amount. The other major source of computational effort is setting up and storing the various matrices used in the problem. For the range of test cases we considered, the solution of the sparse linear systems only took 5–10% of the total computational time. Other methods, such as those based on splines, will have comparable setup time, but longer solution time for the corresponding dense linear system.

In Table VI, the effect of truncating the matrix $\mathbf{A}$ on the convergence of the solution is illustrated for various threshold levels with a lab energy of 800 MeV. This calculation was performed using the Daubechies-3 wavelets with $M_k = M_n = 6$. Comparing these results with those in Table III, we see that even keeping just one percent of the matrix elements we are able to reproduce the T-matrix to the same precision as the accuracy of the untruncated matrix.

Finally, we consider the accuracy of the phase shifts determined by our momentum vector approach. To calculate the phase shifts we project our T-matrix onto the partial waves using

$$T_l(p') = 2\pi \int_{-1}^{1} P_l(x') T(p', p_0, x') dx'.$$  

We compute the integrals using 20 Gauss-Legendre

VII. CONCLUSIONS

We have shown that it is possible to use wavelets to calculate the two-body scattering matrix in terms of momentum vectors without resorting to partial waves. We were able to accurately reproduce the phase shifts of the Malfliet-Tjon potential. These calculations lead to sparse matrices, which can be efficiently inverted using standard iterative methods. Application of a simple preconditioning matrix was shown to be necessary to achieve convergence of the iterative methods. Traditional methods for solving scattering equations in momentum space typically produce dense matrices that require a large amount of storage and are time consuming to invert. These are promising results because relativistic scattering equations are naturally formulated in momentum space. Also, the scattering boundary conditions are most easily treated in momentum space. Wavelet methods can help treat both of these problems.

One of the main advantages of wavelet methods over methods such as splines is that the wavelet transform presents a method that automatically determines what basis functions are necessary for a given accuracy. Unfortunately, this also leads to one of the main drawbacks of this method. In our procedure, a large dense matrix, $A$, needs to be produced first and then this is transformed to a sparse matrix. Most of the computational time is spent constructing and transforming this matrix into a sparse format. The subsequent solution of the sparse linear system takes relatively little computational effort.

For this specific problem, wavelet methods based on momentum vectors may not be necessary. The maximum number of partial waves that needs to be included to achieve convergence, $l_{\text{max}} = 14$ [4], is simply too small to gain a computational benefit from using wavelets in the angular variable. To achieve a computational benefit we should use less basis functions in the angular variable than the maximum number of partial waves. In the three-body problem or at much higher energies, the number of partial waves that need to be included increases considerably and computational benefits may be gained from employing a momentum vector approach.

APPENDIX A: COMPLEX BICONJUGATE GRADIENT METHOD

The biconjugate gradient method [7, 15] is an iterative technique for solving large matrix equations of the form

$$Ax = b.$$ 

The advantage of this method for large sparse matrices is that it only involves matrix multiplication by $A$ and its adjoint, both of which can be accomplished efficiently in a sparse storage format such as CCS [14]. The algorithm generates a sequence of approximate solutions, $x_k$, with residual $r_k = b - Ax_k$. One iterates until the norm of the residual is less than some predetermined value.

This method is traditionally formulated for real matrices, but the extension to complex matrices is straightforward.
ward. Below we present the algorithm for general complex matrices. For our calculations, we start with the initial approximate solution

\[ x_0 = b \]

with the residual

\[ r_0 = b - Ax_0 . \]

For the initial values of the bi-residual \( r_0 \), the direction vector \( p_0 \), and bi-direction \( \bar{p}_0 \) we use

\[ r_0 = b - A^\dagger x_0 \]
\[ p_1 = r_0 \]
\[ \bar{p}_1 = r_0 . \]

Then we use the recurrence relations

\[ \alpha_k = \frac{\bar{r}_k \bar{r}_{k-1}}{p_k^\dagger A p_k} \]
\[ x_k = x_{k-1} + \alpha_k p_k \]
\[ r_k = r_{k-1} - \alpha_k A p_k \]
\[ \bar{r}_k = r_{k-1} - \alpha_k A^\dagger \bar{p}_k \]
\[ \beta_k = \frac{\bar{r}_k \bar{r}_k}{\bar{r}_{k-1} \bar{r}_{k-1}} \]
\[ p_{k+1} = r_k + \beta_k p_k \]
\[ \bar{p}_{k+1} = \bar{r}_k + \beta_k \bar{p}_k . \]

to generate an improved approximation. This is repeated until the desired accuracy is obtained. We measure the accuracy by the \( \ell^2(C) \) norm of the residual,

\[ e_k = \| \bar{r}_k \| = \sqrt{\bar{r}^\dagger \bar{r}} . \]
